- **This version was published on October 30 2023**

This is an open-source introduction to Git and GitHub guide that will help you learn the basics of version control and start using Git for your SysOps, DevOps, and Dev projects. No matter if you are a DevOps/SysOps engineer, developer, or just a Linux enthusiast, you can use Git to track your code changes and collaborate with other members of your team or open source maintainers.

The guide is suitable for anyone working as a developer, system administrator, or a DevOps engineer and wants to learn the basics of Git and GitHub.

My name is Bobby Iliev, and I have been working as a Linux DevOps Engineer since 2014. I am an avid Linux lover and supporter of the open-source movement philosophy. I am always doing that which I cannot do in order that I may learn how to do it, and I believe in sharing knowledge.

I think it's essential always to keep professional and surround yourself with good people, work hard, and be nice to everyone. You have to perform at a consistently higher level than others. That's the mark of a true professional.

For more information, please visit my blog at <https://bobbyiliev.com>, follow me on Twitter [@bobbyiliev_](#) and [YouTube](#).

This book is made possible thanks to these fantastic companies!

DigitalOcean is a cloud services platform delivering the simplicity developers love and businesses trust to run production applications at scale.

It provides highly available, secure, and scalable compute, storage, and networking solutions that help developers build great software faster.

Founded in 2012 with offices in New York and Cambridge, MA, DigitalOcean offers transparent and affordable pricing, an elegant user interface, and one of the largest libraries of open source resources available.

For more information, please visit <https://www.digitalocean.com> or follow [@digitalocean](#) on Twitter.

If you are new to DigitalOcean, you can get a free \$200 credit and spin up your own servers via this referral link here:

Welcome to this Git and GitHub basics training guide! In this **Git crash course**, you will learn the **basics of Git** so you can use Git to track your code changes and collaborate with other members of your team or open source maintainers.

Whether you are a newcomer to programming, or an experienced one, you have to know how to use Git. Most of the projects that a small or big group of developers work on are done through GitHub or GitLab.

It makes working with other developers so much more exciting and enjoyable, just by creating a new branch, adding all your brilliant ideas to the code that can help the project, committing it, and then pushing it to GitHub or GitLab. Then after the PR(pull request) has been opened, reviewed, and then merged, you can get back to your code and continue adding more awesome stuff. After pulling the changes from the main/master branch, of course.

If what you just read doesn't make any sense to you, don't worry. Everything will be explained in this eBook!

This eBook will show you the basics of how to start using Git and try to help you get more comfortable with it.

It does look a bit scary in the beginning, but don't worry. It's not as frightening as it seems, and hopefully, after reading this eBook, you can get a bit more comfortable with Git.

Learning Git is essential for every programmer. Even some of the biggest companies use GitHub for their projects. Remember that the more you use it, the more you're going to get used to it.

[Git](#) is without a doubt the most popular open-source version control system for tracking changes in source code out there.

The original author of git is [Linus Torvalds](#), who is also the creator of **Linux**.

Git is designed to help programmers coordinating work with each other. Its goals include speed, data integrity, and support for distributed workflows.

Version control, also called *Source control*, allows you to track and manage all of the changes to your code.

- Multiple people could work on the same project simultaneously.
- Serves simultaneously as a repository, project narrative, communication medium, and team and product management tool.
- Records all changes in a log
- Allows team members to work concurrently and provides the facility to merge that work back together.
- Traces each change made to the software.
- Data is transitory and can be lost easily.

Also known as a source code manager (SCM) or a revision control system (RCS), it is a system that keeps track of changes to a file or set of files and in case of any problems, lets you go back in history, comparing changes over time, and easily revert to a working state of your source code. SVN, Mercurial, and the massively popular Git are popular version control systems for developers. All of these are free and open-source.

With distributed version control systems like Git, you would have your source code stored on a remote repository like GitHub and also a local repository stored on your computer.

You will learn more about remote and local repositories in the next few chapters. Still, one of the main points for the moment is that your source code would be stored on a remote repository, so in case that something goes wrong with your laptop, you would not lose all of your changes, but they will be safely stored on GitHub.

In order for you to be able to use Git on your local machine, you would need to install it.

Depending on the operating system that you are using, you can follow the steps here.

With most Linux distributions, the Git command-line tool comes installed out of the box.

If this is not the case for you, you can install Git with the following command:

- On RHEL Linux:

```
sudo dnf install git-all
```

- On Debian based distributions including Ubuntu:

```
sudo apt install git-all
```

If you are using Mac, Git should be available out of the box as well. However, if this is not the case, there are 2 main ways of installing Git on your Mac:

- Using Homebrew: in case that you are using Homebrew, you can open your terminal and run the following:

```
brew install git
```

- Git installer: Alternatively, you could use the following installer:

[git-osx-installer](#)

I would personally stick to Homebrew.

If you have a Windows PC, you can follow the steps on how to install Git on Windows [here](#):

[Install Git on Windows](#)

During the installation, make sure to choose the Git Bash option, as this would provide you with a Git Bash terminal which you will use while following along.

Once you have installed Git, in order to check the version of Git that you have installed on your machine, you could use the following command:

```
git --version
```

Example output:

```
git version 2.25.1
```

In my case, I have Git 2.25.1 installed on my laptop.

As throughout this eBook, we will be using mainly Git via the command line. It is important to know basic shell commands so that you could find your way around the terminal.

So before we get started, let's go over a few basic shell commands!

ls

The `ls` command allows you to list the contents of a folder/directory. All that you need to do in order to run the command is to open a terminal and run the following:

```
ls
```

The output will show you all of the files and folders that are located in your current directory. In my case, starting from the root directory of this project, the output is the following:

```
CONTRIBUTING.md LICENSE README.md ebook index.html
```

From the output, we can see that `CONTRIBUTING.md`, `LICENSE`, `README.md`, `index.html` are files, while `ebook` is a subdirectory/subfolder.

For more information about the `ls` command, make sure to check out this page [here](#).

Note: This will work on a Linux/UNIX based systems. If you are on Windows and if you are using the built-in CMD, you would have to use the `dir` command.

cd

The `cd` command stands for **C**hange **D**irectory and allows you to navigate through the filesystem of your computer or server. Let's say that I wanted to go inside the `ebook` directory from the output above. What I would need to do is to run the `cd`

command followed by the directory that I want to access:

```
cd ebook
```

If I wanted to go back one level up, I would use the `cd ..` command. After doing so, I should be one level up from the `ebook` directory and back in the root directory of my project.

`pwd`

The `pwd` command stands for **Print Working Directory** which essentially means that when you run the command, it will show you the current directory that you are in.

Let's take the example from above. If I run the `pwd` command, I would get the full path to the folder that I'm currently in:

```
pwd
```

Output:

```
/home/bobby/introduction-to-git
```

Then I could use the `cd` command and access the `ebook` directory:

```
cd ebook
```

And finally, if I was to run the `pwd` command again, I would see the following output:

```
/home/bobby/introduction-to-git/ebook
```

Essentially what happened was that thanks to the `pwd` command, I was able to see that I'm at the `/home/bobby/introduction-to-git` directory and then after accessing the `ebook` directory, again by using `pwd` I was able to see that my new

current directory is `/home/bobby/introduction-to-git/ebook`.

`rm`

The `rm` command stands for **remove** and allows you to delete files and folders. Let's say that I wanted to delete the `README.md` file, what I would have to do is run the following command:

```
rm README.md
```

In case that I had to delete a folder/directory, I would need to specify the `-r` flag:

```
rm -r ebook
```

Note: keep in mind that the `rm` command would completely delete the files and folders, and the action is irreversible, meaning that you can't get them back.

`mkdir`

The `mkdir` command stands for **make directory** and is used for creating one or more new directories. All you need to do in order to create a new directory using this command is to open a terminal, `cd` into desired location and run the following:

```
mkdir My_New_Directory
```

The above command will create a new, empty directory called `My_New_Directory`.

You can also create several new directories by placing the names of desired directories after each other:

```
mkdir My_New_Directory My_Another_New_Directory
```

touch

The **touch** command is used to update timestamps on files. A useful feature of the touch command is that it will create an empty file. This is useful if you want to create file in your directory that doesn't currently exist:

```
touch README.md
```

The above will create a new, empty file with the name README.md

One thing that you need to keep in mind is that all shell commands are case sensitive, so if you type **LS** it would not work.

With that, now you know some basic shell commands which will be beneficial for your day-to-day activities.

The first time you set up Git on your machine, you would need to do some initial configuration.

There are a few main things that you would need to configure:

- Your details: like your name and email address
- Your Git Editor
- The default branch name: we will learn more about branches later on

We can change all of those things by using the `git config` command.

Let's get started with the initial configuration!

`git config`

In order to configure your Git details like your user name and your email address, you need to use the following command:

- Configuring your Git user name:

```
git config --global user.name "Your Name"
```

- Configuring your Git email address:

```
git config --global user.email johndoe@example.com
```

Usually, it is good to have a matching user name and email for your local Git configuration and your GitHub profile details

- Configuring your Git default editor

In some cases, when running Git commands via your terminal, an editor will open where you could type a commit message, for example. To specify your default editor,

you need to run the following command:

```
git config --global core.editor nano
```

You can change the **nano** editor with another editor like **vim** or **emacs** based on your personal preferences.

- Configuring the default branch name

Whenever creating a new repository on your local machine, it gets initialized with a specific branch name which might be different from the default branch on GitHub. To make sure that the branch name on your local machine matches the default branch name on GitHub, you can use the following command:

```
git config --global init.defaultBranch main
```

Finally, once you are done with all changes, you can check your current Git configuration with the following command:

```
git config --list
```

Example output:

```
user.name=Bobby Iliev  
user.email=bobby@bobbyiliev.com  
core.repositoryformatversion=0  
core.filemode=true  
core.bare=false  
core.logallrefupdates=true
```

~/.gitconfig

As we used the **--global** option in our commands, all of those Global Git settings would be stored in a `.gitconfig` file inside your home directory.

We can use the **cat** command to check the content of the file:

```
cat ~/.gitconfig
```

Example output:

```
[user]
  name = Bobby Iliev
  email = bobby@bobbyiliev.com
```

You can even change the file manually with your favorite text editor, but I personally prefer to use the `git config` command to prevent any syntax problems.

So far we have been using the `--global` option with all of our changes to our git configurations and this results in any configuration changes applying to all repositories. You might however want to change the configuration for only one specific repository. You can do this easily by running the same git config commands mentioned earlier but with out the `--global` option. This will save the changes for only the repository you are currently in and leave your global settings the same as they were before.

`.git`

Whenever you initialize a new project or clone one from GitHub, it would have a `.git` directory where all of the Git commits would be recorded at and also a `config` file where the configuration settings for the particular project would be stored at.

You could use the `ls` command to check the contents of the `.git` folder:

```
ls .git
```

Output:

```
COMMIT_EDITMSG  HEAD  branches  config  description  hooks
index  info  logs  objects  refs
```

Note: Before running the command, you would need to be inside your project's directory. We will learn about this in the next chapters when we learn more about the `git init` command and cloning an existing repository from GitHub with the `git clone` command.

Before we deep dive into all of the various Git commands, let's quickly get familiar with GitHub.

Git is essentially the tool that you use to track your code changes, and GitHub, on the other side, is a website where you can push your local projects to.

This is essentially needed as it would act as a central hub where you would store your projects and all of your teammates or other people working on the same project as you would push their changes to.

Before you get started, you would need to create an account with GitHub. You can do so via this link here:

- [Join GitHub](#)

You will get to the following page where you will need to add your new account details:

Once you've registered, you can go to https://github.com/YOUR_USER_NAME, and you will be able to see your public profile where you can add some information about yourself. Here is an example profile which you can check: [GitHub Profile](#)

If you are not familiar with the word repository, you can think of it as a project. It would hold all of the files of your application or website that you are building. People usually call their repository a repo for short.

To create a new repository on GitHub, you have to click on the + sign on the top right

corner or click on the green **NEW** button in the top-left where repositories are mentioned and then click on the **New Repository** button:

After that, you'll get to a page where you can specify the information for your new repository like:

- The name of the project: Here, make sure to use something descriptive
- Some general description about the project and what it is about
- Choose whether you want the repository to be Public or Private

Once you've added the necessary information and hit the create button, you will get to a page with some instructions on how to push your local project to GitHub:

We will go over those steps more in-depth in the next few chapters.

Depending on the project and whether or not it is open source, you can set your repository to be **public** or **private**.

The main difference is that, with a public repository anyone on the internet can see that repository. Even though they'll be able to see the repository and read the code, you will be the maintainer of the project, and you will choose who can commit.

Whereas a private repository will only be accessible to you and those you have invited.

Public repositories are used for open source projects.

Colaborators are the people who actively work on the project, for example if a company has taken up a project for which some x, y, z are supposed to work, so these people are added as a colaborator by the the company.

Select a GitHub repository and navigate to the settings tab, in the left side menu bar there is an option **Manage access**, there you can add the collaborators for your project.

The **README.md** file is an essential part of each project. The **.md** extension stands for Markdown.

You can think of the **README.md** file as the introduction to your repository. It's beneficial because while looking at someone's repo, you can just scroll down to their README file and have a look at what their project is all about.

And it is crucial that your project is properly introduced. Because if the project itself isn't introduced properly, no one will spend their time helping to improve it and try to develop it further.

That's why having a good README file is necessary and it shouldn't be overlooked, and you should spend a considerable amount of your time on it.

In this post, I am going to share some tips with you about how you can improve your README file, and hopefully, it will help you with your repositories.

For more information, make sure to check out this post on [how to write a good README.md file](#).

Let's start by answering the question why do we star a repository?

Firstly people star a repository for later use or maybe just to keep track of it. I would basically star a repository because I might be needing it for later use.

For instance repository like the [introduction-to-git-and-github-ebook](#) is essential because you might get stuck on Git as a beginner and you can just simply refer to it easily.

And secondly its used to show support to the creator and the maintainers of the repository.

So lets use this eBook [introduction-to-git-and-github-ebook](#) as an example to actually star a repository.

You have visit GitHub and find the [introduction-to-git-and-github-ebook](#) reposotory via the search, or access the repository directly at:

<https://github.com/bobbyiliev/introduction-to-git-and-github-ebook>

Updated 2 hours ago

Now while you are on the repository page on GitHub, at the top of the page where the **USERNAME/THE REPOSITORY NAME** lies, you will find some couple of icon:

Click on the star icon and you have successfully starred the project.

Whenever you like a project and want to suport the creator, make sure to click star the repository! Just like you would enjoy a video on YouTube and hit the like button.

If you are starting a new project or if you have an existing project which you would like to add to Git and then push to GitHub, you need to initialize a new Git project with the `git init` command.

To keep things simple, let's say that we want to start building a fresh new project. The first thing that I would usually do is to create a new folder where I would store my project files at. To do that, I can use the `mkdir` command followed by the name of the folder, which will create a new empty directory/folder:

```
mkdir new-project
```

The above command will create a folder called `new-project`. Then as we learned in chapter 4, we can use the `cd` command to access the directory:

```
cd new-project
```

After that, by using the `ls` command, we will be able to verify that the directory is completely empty:

```
ls -lah
```

Then with that, we are ready to initialize a new Git project:

```
git init
```

You will get the following output:

```
Initialized empty Git repository in /home/devdojo/new-  
project/.git/
```

As you can see, what the `git init` command does is to create a new `.git` folder which we already discussed in chapter 5.

With that, you've successfully created a new empty Git project! Let's move to the next chapter, where you will learn how to use the `git status` command to check the current status of your repository.

Whenever you make changes to your Git project, you would want to verify what has changed before making a commit or before pushing your changes to GitHub, for example.

To check the current status of your project, you can use the `git status` command. If you run the `git status` command in the same directory where you initialized your Git project from the last chapter, you will see the following output:

```
On branch main

No commits yet

nothing to commit (create/copy files and use "git add" to track)
```

As this is a fresh new repository, there are no commits and no changes yet. So let's go ahead and create a `README.md` file with some generic content. We can run the following command to do so:

```
echo "# Demo Project" >> README.md
```

What this would do is to output the `# Demo Project` and store it in the `README.md` file.

If you run `git status` again, you will then see the following output:

```
Untracked files:
  (use "git add <file>..." to include in what will be committed)
        README.md
nothing added to commit but untracked files present (use "git add" to track)
```

As you can see, Git is detecting that there is 1 new file that is not tracked at the

moment called `README.md`, which we just created. And already, Git is prompting us to use the `git add` command to start tracking the file. We will learn more about the `git add` command in the next chapter!

We are going to be using the `git status` command throughout the next few chapters a lot! This is particularly helpful, especially when you've modified a lot of files and you want to check the current status and see all of the modified, updated, or deleted files.

By default, when you create a new file inside your Git project, it is not being tracked by Git. So to tell git that it should start tracking the file, you need to use the `git add` command.

The syntax is the following:

```
git add NAME_OF_FILE
```

In our case, we have only 1 file inside our project called `README.md`, so to add this file to Git, we can use the following command:

```
git add README.md
```

If you then run `git status` again, you will see a different output:

```
Changes to be committed:
  (use "git rm --cached <file>..." to unstage)
    new file:   README.md
```

Here you would see that there are now some changes staged and ready to be committed. Also, Git tells us that the `README.md` is a new file that was just staged and has not been tracked before.

In case that you have a couple of files, you could list them all divided by space after the `git add` command to stage them all rather than running `git add` multiple times for each individual file:

```
git add file1.html file2.html file3.html
```

With the above, we will add the 3 files by running `git add` just once, however in some cases, you might have a lot of new files, and adding them one by one could be

highly time-consuming.

So there is a way to stage absolutely all files in your current project, and this is by specifying a dot after the `git add` command as follows:

```
git add .
```

Note: You need to be careful with this as in some cases, there might be some files that you don't want to add to Git.

With that, we are ready to move on and learn about the `git commit` command.

Once you have added/staged your files, the next step is actually to commit the changes. So if you run `git status` again, you will be able to see that Git tells us that there are changes to be committed:

```
Changes to be committed:
  (use "git rm --cached <file>..." to unstage)
    new file:   README.md
```

In this case, it is only the `README.md` file that will be committed. So in order to do so, we can run the following command:

```
git commit -m "Your Commit Message Here"
```

Rundown of the command:

- `git commit`: here, we are telling git that we want to commit the changes that we've staged with the `git add` command
- `-m`: this flag indicates that we will specify our commit message directly after that
- Finally, in the quotes we've got our commit message, it is important to write short and descriptive commit messages

In our case we could set our commit message to something like `"Initial commit"` or `"Add README.md"` file, for example.

If you don't specify the `-m` flag, Git will open the default text editor that we've configured in chapter 5 where you will be able to type the commit message directly.

Committing directly without staging files:

If you have not already staged your changes using `git add` command you can still directly commit all your changes using the following command.

```
git commit -a -m "Your Commit Message Here"
```

The `-a` flag here will automatically stage all the changes and commit them.

Git allows you to sign your commits. Commits signed with a verified signature in GitHub and GitLab display a verified label as shown below. 

To sign commits, first you need to:

- make sure that you have GNU GPG installed on your host.
- Generate a GPG signing key pair if you don't already have

```
gpg --full-generate-key
```

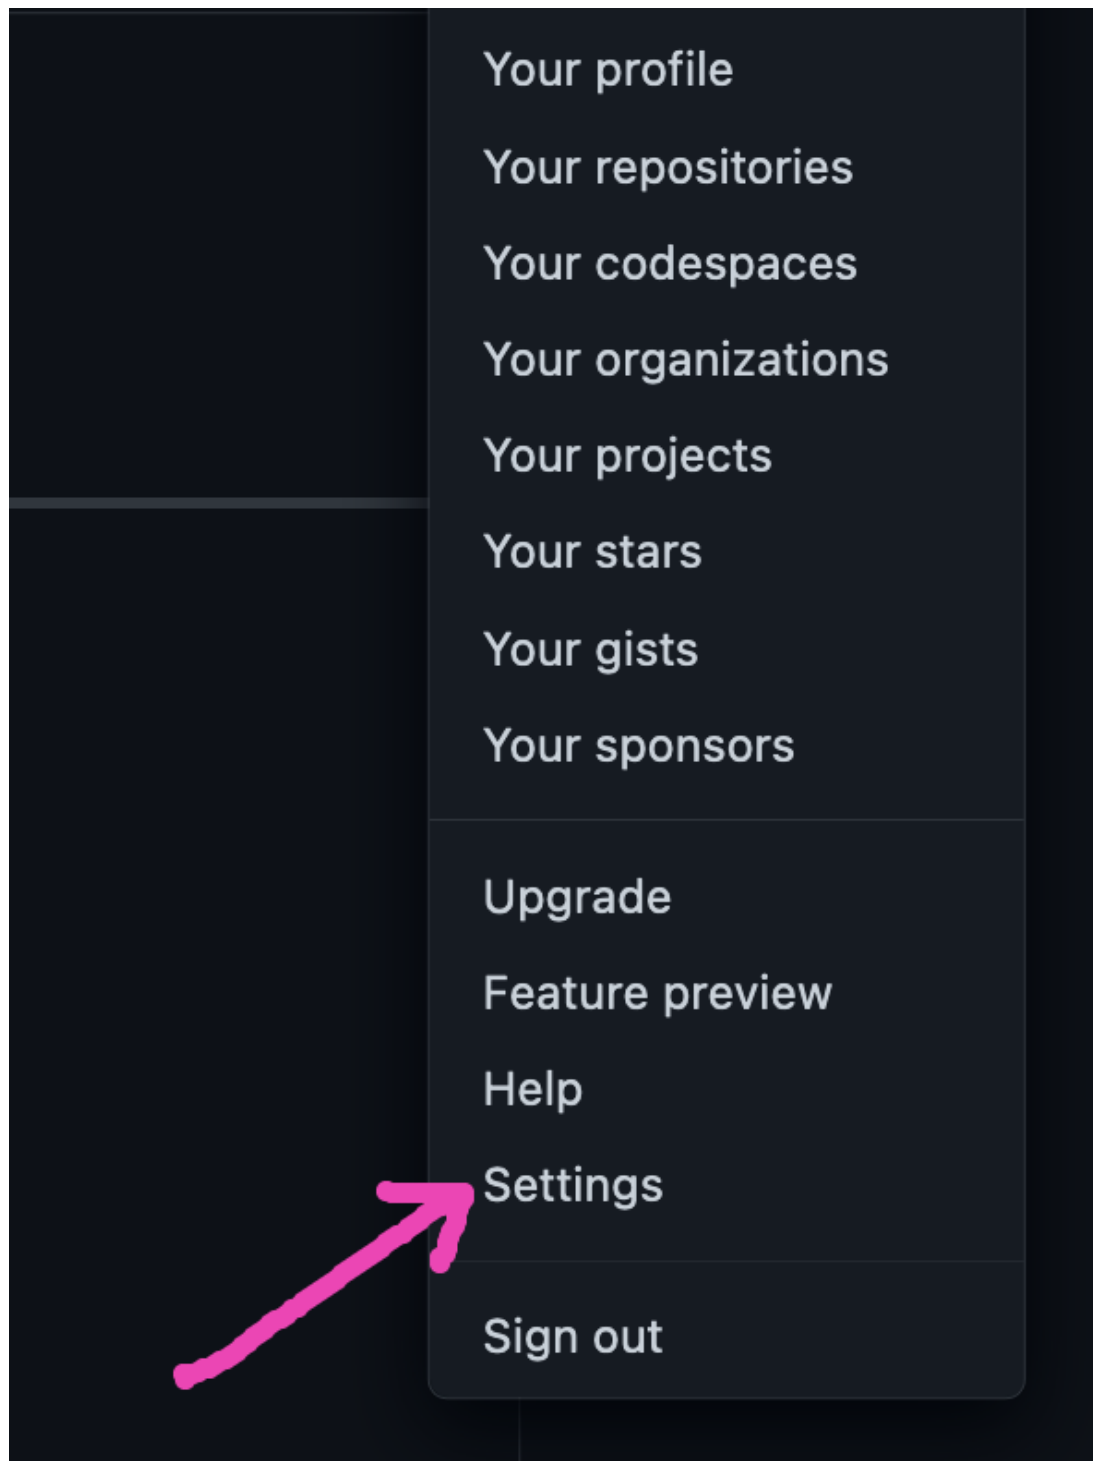

- Use the `gpg --list-secret-keys --keyid-format=long` command to list the long form of the GPG keys

```
gpg --list-secret-keys --keyid-format=long
/Users/bobby/.gnupg/pubring.kbx
-----
sec   rsa4096/E630A0A00CAA7AAA 2021-10-01 [SC] [expires:
2026-10-01]
      5F1F417F8A043C888888888888E630F6D35CFA7ECD
uid           [ultimate] Bobby Illiev (For signing git
commits) <bobby@bobbyiliev.com>
ssb   rsa4096/46EE4AA180001AA6 2021-10-01 [E] [expires:
2026-10-01]
```

- Copy the long form of the GPG key ID you'd like to use. In this sample, the GPG key ID is `E630A0A00CAA7AAA`.
- Export the public key:

```
gpg --armor --export E630A0A00CAA7AAA
```

- Copy your GPG key, beginning with `-----BEGIN PGP PUBLIC KEY BLOCK-----` and ending with `-----END PGP PUBLIC KEY BLOCK-----`.
- Login to GitHub or GitLab and add a new GPG key under settings:

- Set your GPG signing key in Git: (If you intend to add the signing key per repository, the omit the `--global` flag)

```
git config --global user.signingkey E630A0A00CAA7AAA
```

- Enable automatic signing for all commits:

```
git config --global commit.gpgsign true
```

- Or Sign per commit by passing `-S` option to `git commit`:

```
git commit -S -m "your commit message"
```

After running the `git commit` command, we can use the `git status` command again to check the current status:

```
git status
```

Output:

```
On branch main
nothing to commit, working tree clean
```

As you can see, Git is telling us that there are no changes to be committed as we've already committed them.

Let's go ahead and make another change to the `README.md` file. You can open the file with your favorite text editor and make the change directly, or you can run the following command:

```
echo "Git is awesome!" >> README.md
```

The above would add a new line at the bottom of the `README.md` file. So if we were to run `git status` again, we will see the following output:

```
On branch main
Changes not staged for commit:
  (use "git add <file>..." to update what will be committed)
  (use "git restore <file>..." to discard changes in working
  directory)
        modified:   README.md

no changes added to commit (use "git add" and/or "git commit -
a")
```

As you can see, Git has detected that the `README.md` file has been modified and is also prompting us to use the command that we've learned to first stage/add the file!

In case that you wanted to change your last commit message, you can run the `git commit --amend` command. This will open the default editor where you can change your commit message. Also, this allows you to change the commit changes.

The `git status` command gives us a great overview of the files that have changed, but it does not show us what the changes actually are. In the next chapter, we are going to learn how to check the differences between the last commit and the current changes.

To check for commits that changed particular file you can use the `--follow` flag:

```
git log --follow [file]
```

The above shows the commits that changed the file, even across renames.

As mentioned in the last chapter, the `git status` command gives us a great overview of the files that have changed, but it does not show us what the changes actually are.

You can check the actual changes that were made with the `git diff` command. If we were to run the command in our repository, we would see the following output:

```
diff --git a/README.md b/README.md
index 9366068..2b14655 100644
--- a/README.md
+++ b/README.md
@@ -1,2 @@
 # Demo Project
+Git is awesome
```

As we only changed the `README.md` file, Git is showing us the following:

- `diff --git a/README.md b/README.md`: here git indicates that it shows the changes made to the `README.md` file since the last commit compared to the current version of the file.
- `@@ -1,2 @@`: here git indicates that 1 new line was added
- `+Git is awesome`: here, the important part is the `+`, which indicates that this is a new line that was added. In case that we remove a line, you would see a `-` sign instead.

In our case, as we only added 1 new line to the file, Git indicates that only 1 file was changed and that only 1 new line was added.

Next, let's go ahead and stage that change and commit it with the comments that we've learned from the previous chapters!

- Stage the changed file:

```
git add README.md
```

- Then again run `git status` to check the current status:

```
git status
```

The output would look like this, indicating that there is 1 modified file:

```
On branch main
Changes to be committed:
  (use "git restore --staged <file>..." to unstage)
    modified:   README.md
```

- Commit the changes:

```
git commit -m "Update README.md"
```

Finally, if you run `git status` again you will see that there are no changes to be committed.

I always run `git status` and `git diff` before making any commits, just so that I'm sure what has changed.

Note 1 : `git diff --staged` will only show the changes to the file in "staged" area.

Note 2 : `git diff HEAD` will show all changes to tracked files(file in last snapshot), if you have all the changes staged for commit then both the commands give same output.

In some cases, you would like to see a list of the previous commits. We will learn how to do that in the next chapter.

In order to list all of the previous commits, you can use the following command:

```
git log
```

This will provide you with your commit history, the output would look like this:

```
commit da46ce39a3fd663ff802d013f834431d4b4159a5 (HEAD -> main)
Author: Bobby Iliev <bobby@bobbyiliev.com>
Date:   Fri Mar 12 17:14:02 2021 +0000

    Update README.md

commit fa583473b4be2807b45f35b755aa84ac78922259
Author: Bobby Iliev <bobby@bobbyiliev.com>
Date:   Fri Mar 12 17:01:17 2021 +0000

    Initial commit
```

The entries are listed, in order, from most recent to oldest.

Rundown of the output:

- **commit da46ce39a3fd663ff802d013f834431d4b4159a5**: Here you can see the specific commit ID
- **Author: Bobby Iliev...** : Then you can see who created the changes
- **Date: Fri Mar 12...**: After that, you've got the exact time and date when the commit was created
- Finally, you have the commit message. This is one of the reasons why it is important to write short and descriptive commit messages so that later on, you could tell what changes were introduced by the particular commit.

If you want to check the differences between the current state of your repository and a particular commit, what you could do is use the **git diff** command followed by the commit ID:

```
git diff fa583473b4be2807b45f35b755aa84ac78922259
```

In my case the output will be the following:

```
diff --git a/README.md b/README.md
index 9366068..2b14655 100644
--- a/README.md
+++ b/README.md
@@ -1,2 @@
-# Demo Project
+Git is awesome
```

So the difference between that specific commit and the current state of the repository is the change in the **README.md** file.

In case that you wanted to see only the commit IDs and commit messages on one line, you could add the **--oneline** argument:

```
git log --oneline
```

Output:

```
* da46ce3 (HEAD -> main) Update README.md
* fa58347 Initial commit
```

With that, you now know how to check your commit history! Next, let's go ahead and learn how to exclude specific files from Git!

While working on a Git repository, you will often have files and directories that you do not want to commit, so that they are not available to others using the repository.

In some cases, you might not want to commit some of your files to Git due to security reasons.

For example, if you have a config file that stores all of your database credentials and other sensitive information, you should never add it to Git and push it to GitHub as other people will be able to get hold of that sensitive information.

Another case where you may not want to commit a file or directory, is when those files are automatically generated and do not contain source code, so that you don't clutter your repository. Also, sometimes it makes sense not to commit certain files that contain environment information, so that other people can use your code with their environment files.

To prevent these types of files from being committed, you can create a `gitignore` file which includes a list of all of the files and directories that should be excluded from your Git repository. In this chapter, you will learn how to do that!

Let's have a look at the following example if you had a `PHP` project and a file called `config.php`, which stores your database connection string details like username, password, host, etc.

To exclude that file from your git project, you could create a file called `.gitignore` inside your project's directory:

```
touch .gitignore
```

Then inside that file, all that you need to add is the name of the file that you want to ignore, so the content of the `.gitignore` file would look like this:

```
config.php
```

That way, the next time you run `git add .` and then run `git commit` and `git push`, the `config.php` file will be ignored and will not be added nor pushed to your Github repository.

That way, you would keep your database credentials safe!

In some cases, you might want to ignore a whole folder. For example, if you have a huge `node_modules` folder, there is no need to add it and commit it to your Git project, as that directory is generated automatically whenever you run `npm install`.

The same would go for the `vendor` folder in Laravel. You should not add the `vendor` folder to your Git project, as all of the content of that folder is generated automatically whenever you run `composer install`.

So to ignore the `vendors` and `node_modules` folders, you could just add them to your `.gitignore` file:

```
# Ignored folders
/vendor/
node_modules/
```

Sometimes, you want to ignore a directory except for one or a couple of other files within that directory. It could be that the directory is required for your application to run but the files created is not supposed to be pushed to the remote repository or maybe you want to have a `README.md` file inside the directory for some purpose. To achieve this, your `.gitignore` file should look like this:

```
data/*
!data/README.md
```

The first line indicates that you want to ignore the `data` directory and all files inside it.

However, the second line provides the instruction that the `README.md` is an exception.

Take note that the ordering is important in this case. Otherwise, it will not work.

To get a `gitignore` file for Laravel, you could get the file from [the official Laravel Github repository] here(<https://github.com/laravel/laravel/>).

The file would look something like this:

```
/node_modules
/public/hot
/public/storage
/storage/*.key
/vendor
.env
.env.backup
.phpunit.result.cache
Homestead.json
Homestead.yaml
npm-debug.log
yarn-error.log
```

It essentially includes all of the files and folders that are not needed to get the application up and running.

As the number of frameworks and application grows day by day, it might be hard to keep your `.gitignore` files up to date or it could be intimidating if you had to search for the correct `.gitignore` file for every specific framework that you use.

I recently discovered an open-source project called [gitignore.io](https://github.com/dnclabs/gitignore.io). It is a site and a CLI tool with a huge list of predefined `gitignore` files for different frameworks.

All that you need to do is visit the site and search for the specific framework that you are using.

For example, let's search for a `.gitignore` file for Node.js:

Then just hit the **Create button** and you would instantly get a well documented **.gitignore** file for your Node.js project, which will look like this:

```
# Created by

# End of https://www.toptal.com/developers/gitignore/api/node
```

If you are a fan of the command-line, the gitignore.io project offers a CLI version as well.

To get it installed on Linux, just run the following command:

```
git config --global alias.ignore \
 '!gi() { curl -sL
https://www.toptal.com/developers/gitignore/api/$@ ;}; gi'
```

If you are using a different OS, I would recommend checking out the documentation [here](#) on how to get it installed for your specific Shell or OS.

Once you have the `gi` command installed, you could list all of the available `.gitignore` files from gitignore.io by running the following command:

```
gi list
```

For example, if you quickly needed a `.gitignore` file for Laravel, you could just run:

```
gi laravel
```

And you would get a response back with a well-documented Laravel `.gitignore` file:

```
# Created by
https://www.toptal.com/developers/gitignore/api/laravel
# Edit at
https://www.toptal.com/developers/gitignore?templates=laravel

```

Having a **gitignore** file is essential, it is great that you could use a tool like the [gitignore.io](https://github.com/joshuto/generate-gitignore) to generate your **gitignore** file automatically, depending on your project!

If you like the gitignore.io project, make sure to check out and contribute to the project [here](#).

There are a few ways to authenticate with GitHub. Essentially you would need this so that you could push your local changes from your laptop to your GitHub repository.

You could use one of the following methods:

- HTTPS: Essentially, this would require your GitHub username and password each time you try to push your changes
- SSH: With SSH, you could generate an SSH Key pair and add your public key to GitHub. That way, you would not be asked for your username and password every time you push your changes to GitHub.

One thing that you need to keep in mind is that the GitHub repository URL is different depending on whether you are using SSH or HTTPS:

- HTTPS: `https://github.com/bobbyiliev/demo-repo.git`
- SSH: `git@github.com:bobbyiliev/demo-repo.git`

Note that when you choose SSH, the `https://` part is changed with `git@`, and you have `:` after `github.com` rather than `/`. This is important as this defines how you would like to authenticate each time.

To generate a new SSH key pair in case that you don't have one, you can run the following command:

```
ssh-keygen
```

For security reasons you can specify a passphrase, which essentially is the password for your private SSH key.

The above would generate 2 files:

- 1 **private** SSH key and 1 public SSH key. The private key should always be

stored safely on your laptop, and you should not share it with anyone.

- 1 **public** SSH key, which you need to upload to GitHub.

The two files will be automatically generated at the following folder:

```
~/.ssh
```

You can use the `cd` command to access the folder:

```
cd ~/.ssh
```

Then with `ls` you can check the content:

```
ls
```

Output:

```
id_rsa id_rsa.pub
```

The `id_rsa` is your private key, and again you should not share it with anyone.

The `id_rsa.pub` is the public key that would need to be uploaded to GitHub.

Once you've created your SSH keys, you need to upload the **public** SSH key to your GitHub account. To do so, you first need to get the content of the file.

To get the content of the file, you can use the `cat` command:

```
cat ~/.ssh/id_rsa.pub
```

The output will look like this:

```
ssh-rsa AAB3NzaC1yc2EAAAADAQAB..... your_user@your_host
```

Copy the whole thing and then visit [GitHub](#) and follow these steps:

- Click on your profile picture on the right top
- Then click on settings

- On the left, click on **SSH and GPG Keys**:

- After that, click on the **New SSH Key** button
- Then specify a title of the SSH key, it should be something descriptive, for example: **Work Laptop SSH Key**. And in the **Key** area, paste your public SSH key:

- Finally click the **Add SSH Key** button at the bottom of the page

With that, you now have your SSH Keys generated and added to GitHub. That way, you will be able to push your changes without having to type your GitHub password and user each time.

For more information about SSH keys, make sure to check this tutorial [here](#).

Then finally, once you've made all of your changes, staged them with the `git add .` command, and committed the changes with the `git commit` command, you must push the committed changes from your local repository to your remote GitHub repository. This ensures that the remote repository is brought up-to-date with your local repository.

Before you can push to your remote GitHub repository, you need to first create your remote repository via GitHub as per Chapter 6.

Once you have your remote GitHub repository ready, you can add it to your local project with the following command:

```
git remote add origin  
git@github.com:your_username/your_repo_name.git
```

Note: Make sure to change the `your_username` and `your_repo_name` details accordingly.

This is how you can link your local Git project with your remote GitHub repository.

If you've read the previous chapter, you will most likely notice we are using SSH as the authentication method.

However, if you did not follow the steps from the previous chapter, you can use HTTPS rather than SSH:

```
git remote add origin  
https://github.com/your_username/your_repo_name.git
```

To verify your remote repository, you can run the following command:

```
git remote -v
```

To push your committed changes to the linked remote repository, you can use the `git push` command:

```
git push -u origin main
```

Note: In this command, `-u origin main` tells Git to set the main branch of the remote repository as the upstream branch within the `git push` command. This is the best practice when using Git as it allows the `git push` and `git pull` commands to work as intended. Alternatively, you can use `--set-upstream origin main` for this as well.

If you are using SSH with your SSH key uploaded to GitHub, the push command will not ask you for a password and will push your changes to GitHub straight away.

In case that you did not run the `git remote add` command as outlined in earlier in this chapter, you will receive the following error:

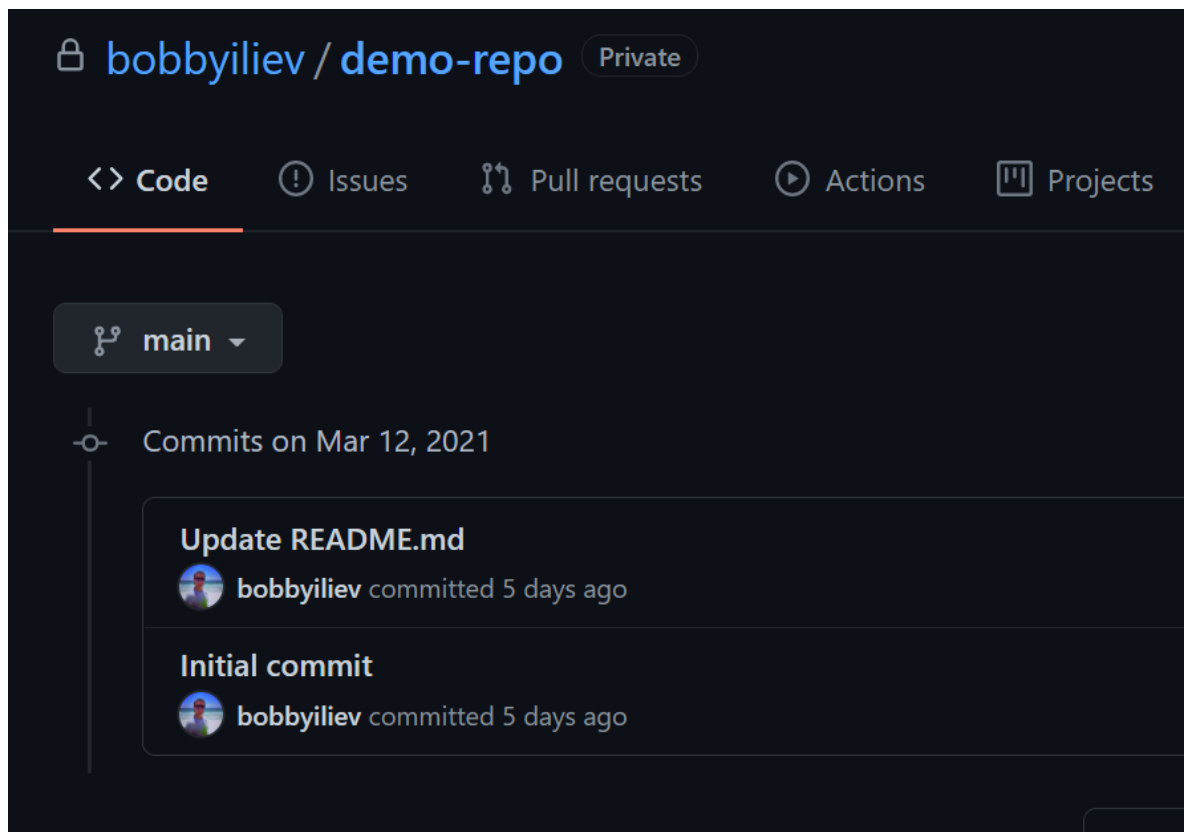

```
fatal: 'origin' does not appear to be a git repository
fatal: Could not read from remote repository.

Please make sure you have the correct access rights
and the repository exists.
```

This would mean that you've not added your GitHub repository as the remote repository. This is why we run the `git remote add` command to create that connection between your local repository and the remote GitHub repository.

Note that the connection would be in place if you used the `git clone` command to clone an existing repository from GitHub to your local machine. We will go through the `git pull` command in the next few chapters as well.

After running the `git push` command, you can head over to your GitHub project and you will be able to see the commits that you've made locally present in remote repository on GitHub. If you were to click on the `commits` link, you would be able to see all commits just as if you were to run the `git log` command:

Now that you know how to push your latest changes from your local Git project to your GitHub repository, it's time to learn how to pull the latest changes from GitHub to your local project.

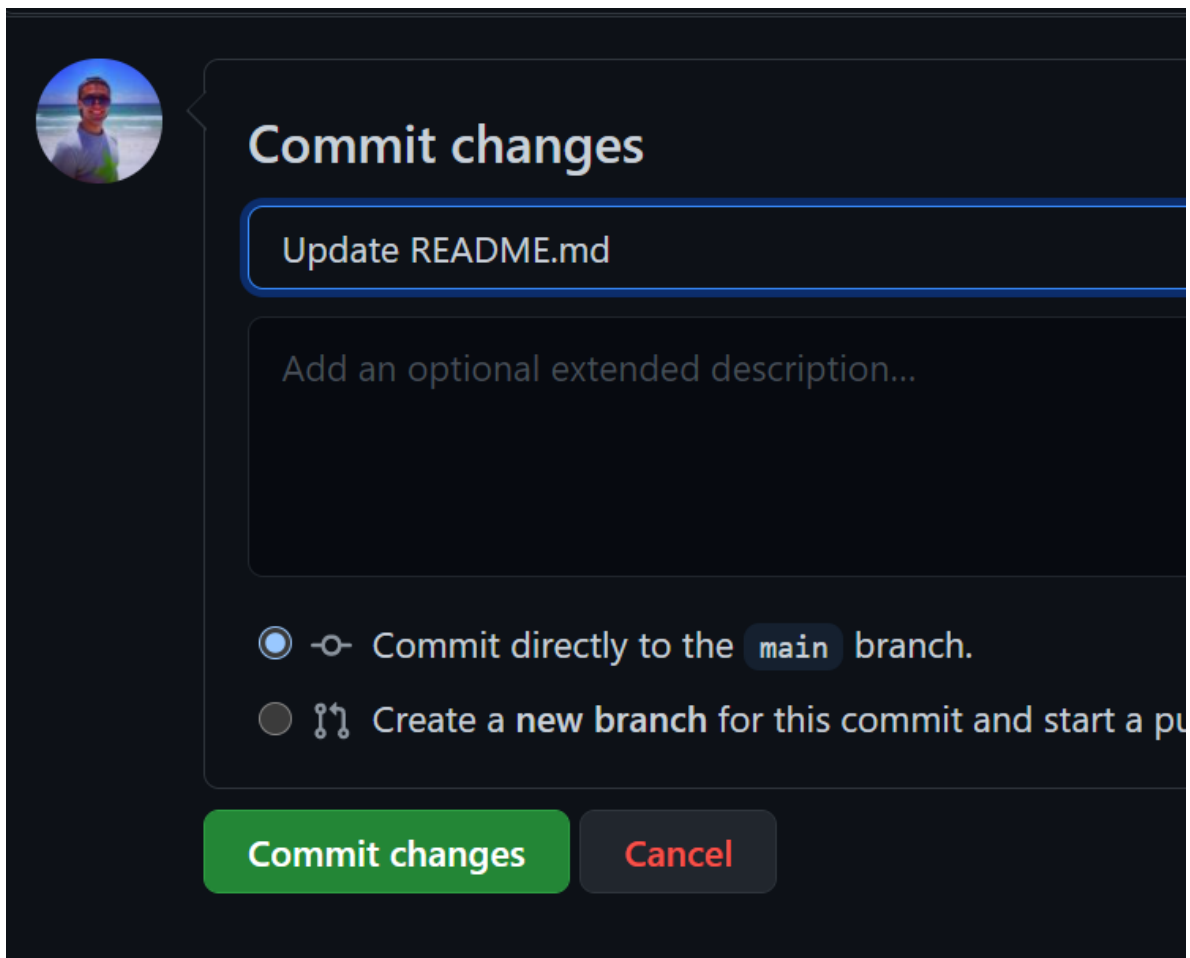

If you are working on a project with multiple people, the chances are that the codebase will change very often. So you would need to have a way to get the latest changes from the GitHub repository to your local machine.

You already know that you can use the `git push` command to push your latest commits, so to do the opposite and pull the latest commits from GitHub to your local project, you need to use the `git pull` command.

To test this, let's go ahead and make a change directly on GitHub directly. Once you are there, click on the `README.md` file and then click on the pencil icon to edit the file:

Make a minor change to the file, add a descriptive commit message and click on the `Commit Changes` button:

A screenshot of the GitHub web interface's 'Commit changes' dialog. On the left is a circular profile picture of a person with glasses and a blue shirt. The main area has a title 'Commit changes' in white. Below it is a text input field containing 'Update README.md'. Underneath is a larger text area with the placeholder 'Add an optional extended description...'. At the bottom, there are two radio button options: the first is selected and says 'Commit directly to the main branch.' (with 'main' in a dark blue pill), and the second is unselected and says 'Create a new branch for this commit and start a pull request'. At the very bottom are two buttons: a green 'Commit changes' button and a grey 'Cancel' button.

 **Commit changes**

Update README.md

Add an optional extended description...

☒ Commit directly to the **main** branch.

☐ Create a new branch for this commit and start a pull request

Commit changes Cancel

With that, you've now made a commit directly on GitHub, so your local repository will be behind the remote GitHub repository.

If you were to try and push a change now to that same branch, it would fail with the following error:

```
! [rejected]        main -> main (fetch first)
error: failed to push some refs to
'git@github.com:bobbyiliev/demo-repo.git'
hint: Updates were rejected because the remote contains work
that you do
hint: not have locally. This is usually caused by another
repository pushing
hint: to the same ref. You may want to first integrate the
remote changes
hint: (e.g., 'git pull ...') before pushing again.
hint: See the 'Note about fast-forwards' in 'git push --help'
for details.
```

As stated in the output, the remote repository is ahead of your local one, so you need to run the `git pull` command to get the latest changes:

```
git pull origin main
```

The output that you will get will look like this:

```
remote: Enumerating objects: 5, done.
remote: Counting objects: 100% (5/5), done.
remote: Total 3 (delta 0), reused 0 (delta 0), pack-reused 0
Unpacking objects: 100% (3/3), 646 bytes | 646.00 KiB/s, done.
From github.com:bobbyiliev/demo-repo
* branch                main          -> FETCH_HEAD
   da46ce3..442afa5      main          -> origin/main

 README.md | 3 ++-
 1 file changed, 2 insertions(+), 1 deletion(-)
```

We can see that the `README.md` file was changed and that there were 2 new lines added and 1 line deleted.

Now, if you were to run `git log`, you will see the commit that you've made on GitHub available locally.

Of course, this is a simplified scenario. In the real world, you would not make any changes directly to GitHub, but you would most likely work with other people on the same project, and you would have to pull their latest changes regularly.

You need to make sure that you pull the latest changes every time before you try to push your changes.

Now that you know the basic Git commands let's go ahead and learn what Git Branches are.

So far, we have been working only on our Main branch, which is created by default when creating a new GitHub repository. In this chapter, you will learn more about Git Branches. Why you need them and how to work with them.

The official definition of a Git branch from the git-scm.com website is the following:

A branch in Git is simply a lightweight movable pointer to one of these commits.

This might be a bit confusing in case that you are just getting started. So you could think of branches as a way to work on your project by adding a new feature or bug fixes without affecting the Main branch.

That way, each new feature or bug fix that you are developing could live on a separate branch, and later on, once you are ready and have fully tested the changes, you can merge the new branch to your main branch. You will learn more about merging in the next chapter!

If we look into the following illustration where we have a few branches, you can see that it looks like a tree, hence the term branching:

Thanks to the multiple branches, you can have multiple people working on different features or fixes at the same time each one working on their own branch.

The image shows 3 branches:

- The main branch
- New Branch 1
- New Branch 2

The main branch is the default branch that you are already familiar with. We can consider the other two branches as two new features that are being developed. One developer could be working on a new contact form for your web application on branch #1, and another developer could be working on a user registration form feature on branch #2.

Thanks to the separate branches, both developers can work on the same project without getting into each others way.

Next, let's go ahead and learn how to create new branches and see this in action!

Let's start by creating a new branch called `newFeature`. In order to create the branch, you could use the following command:

```
git branch newFeature
```

Now, in order to switch to that new branch, you would need to run the following command:

```
git checkout newFeature
```

Note: You can use the `git checkout` command to switch between different branches.

The above two commands could be combined into 1, so that you don't have to create the branch first and then switch to the new branch. You could use this command instead, which would do both:

```
git checkout -b newFeature
```

Once you run this command, you will see the following output:

```
Switched to a new branch 'newFeature'
```

In order to check what branch you are currently on, you can use the following command:

```
git branch
```

Output:

```
main  
* newFeature
```

We can tell that we have 2 branches: the `main` one and the `newFeature` one that we just created. The star before the `newFeature` branch name indicates that we are currently on the `newFeature` branch.

If you were to use the `git checkout` command to switch to the `main` branch:

```
git checkout main
```

And then run `git branch` again. You will see the following output indicating that you are now on the `main` branch:

```
* main  
newFeature
```

Now let's go ahead and make a change on the new feature branch. First switch to the branch with the `git checkout` command:

```
git checkout newFeature
```

Note: we only need to add the `-b` argument when creating new branches

Check that you've actually switched to the correct branch:

```
git branch
```

Output:

```
main
* newFeature
```

Now let's create a new file with some demo content. You can do that with the following command:

```
echo "<h1>My First Feature Branch</h1>" > feature1.html
```

The above will echo out the `<h1>My First Feature Branch</h1>` string and store it in a new file called `feature1.html`.

After that, stage the file and commit the change:

```
git add feature1.html
git commit -m "Add feature1.html"
```

The new `feature1.html` file will only be present on the `newFeature` branch. If you were to switch to the `main` branch and run the `ls` command or check the `git log`, you will be able to see that the file is not there.

You can check that by using the `git log` command:

```
git log
```

With that, we've used quite a bit of the commands that we've covered in the previous chapters!

You can also compare two branches with the following commands.

- Shows the commits on `branchA` that are not on `branchB`:

```
git log BranchA..BranchB
```

- Shows the difference of what is in `branchA` but not in `branchB`:

```
git diff BranchB...BranchA
```

In case that you've created a branch with the wrong name or if you think that the name could be improved as it is not descriptive enough, you can rename a branch by running the following command:

```
git branch -m wrong-branch-name correct-branch-name
```

If you want to rename your **current branch**, you could just run the following:

```
git branch -m my-branch-name
```

After that, if you run `git branch` again you will be able to see the correct branch name.

If you wanted to completely delete a specific branch you could run the following command:

```
git branch -d name_of_the_branch
```

This would only delete the branch from your local repository, in case that you've already pushed the branch to GitHub, you can use the following command to delete the remote branch:

```
git push origin --delete name_of_the_branch
```

If you wanted to synchronize your local branches with the remote branches you could run the following command:

```
git fetch
```

With that, our **newFeature** branch is now ahead of the main branch with 1 commit. So in order to get that new changes over to the main branch, we need to merge the **newFeature** branch into our **main** branch.

In the next chapter, you will learn how to merge your changes from one branch to another!

One thing that you might want to keep in mind is that in the past when creating a new GitHub repository the default branch name was called **master**. However, new repositories created on GitHub use **main** instead of **master** as the default branch name. This is part of GitHub's effort to remove unnecessary references to slavery and replace them with more inclusive terms.

Once the developers are ready with their changes, they can merge their feature branches into the main branch and make those features live on the website.

If you followed the steps from the previous chapter, then your **newFeature** branch is now ahead of the main branch with 1 commit. So in order to get that new changes over to the main branch, we need to merge the **newFeature** branch into our **main** branch.

You can do that by following these steps:

- First switch to your **main** branch:

```
git checkout main
```

- After that, in order to merge your `newFeature` branch and the changes that we created in the last chapter, run the following `git merge` command:

```
git merge newFeature
```

Output:

```
Updating ab1007b..a281d25
Fast-forward
 feature1.html | 1 +
 1 file changed, 1 insertion(+)
 create mode 100644 feature1.html
```

As you were on the `main` branch when you ran the `git merge` command, Git will take all of the commits from that branch and merge them into the `main` branch.

Now, if you run the `ls` command, you will be able to see the new `feature1.html` file, and if you check the commit history with the `git log` command, you will see the commit from the `newFeature` branch present on your `main` branch.

Before doing the merge, you could again use the `git diff` command to check the differences between your current branch and the branch that you want to merge. For example, if you are currently on the `main` branch, you could use the following:

```
git diff newFeature
```

In this case, the merge went through smoothly as there were no merge conflicts. However, if you are working on a real project with multiple people making changes, there might be some merge conflicts. Essentially this happens when changes are made to the same line of a file, or when one developer edits a file on one branch and another developer deletes the same file.

Let's simulate a conflict. To do so, create a new branch:

```
git checkout -b conflictDemo
```

Then edit the `feature1.html` file:

```
echo "<p>Conflict Demo</p>" >> feature1.html
```

The command above will echo out the `<p>Conflict Demo</p>` string, and thanks to the double grater sign `>>`, the string will be added to the bottom of the `feature1.html` file. You can check the content of the file with the `cat` command:

```
cat feature1.html
```

Output:

```
<h1>My First Feature Branch</h1>
<p>Conflict Demo</p>
```

You can again run `git status` and `git diff` to check what exactly has been modified before committing.

After that, go ahead and commit the change:

```
git commit -am "Conflict Demo 1"
```

Note that we did not run the `git add` command, but instead, we used the `-a` flag, which stands for `add`. You can do that for files that have been added to git and have just been modified. If you've added a new file, then you would have to stage it first with the `git add` command.

Now go switch back to your `main` branch:

```
git checkout main
```

And now, if you check the `feature1.html` file, it will only have the `<h1>My First Feature Branch</h1>` line as the change that we made is still only present on the `conflictDemo` branch.

Now let's go ahead and make a change to the same file:

```
echo "<p>Conflict: change on main branch</p>" >> feature1.html
```

Now we are adding again a line to the bottom of the `feature1.html` file with different content.

Go ahead and stage this and commit the change:

```
git commit -am "Conflict on main"
```

Now your `main` branch and the `conflictDemo` branch have changes to the same file, on the same line. So let's run the `git merge` command and see what happens:

```
git merge conflictDemo
```

Output:

```
Auto-merging feature1.html
CONFLICT (content): Merge conflict in feature1.html
Automatic merge failed; fix conflicts and then commit the
result.
```

As we can see from the output, the merge is failing as there were changes to the same file on the same line, so Git is unsure which is the correct change.

As always, there are multiple ways to fix conflicts. Here we will go through one.

Now if you were to check the content of the `feature1.html` file you will see the following output:

```
<h1>My First Feature Branch</h1>
<<<<<<< HEAD
<p>Conflict: change on main branch</p>
=====
<p>Conflict Demo</p>
>>>>>>> conflictDemo
```

Initially, it could be a little bit overwhelming, but let's quickly review it:

- <<<<<<< HEAD: this part here indicates the start of the changes on your current branch. In our case, the <p>Conflict: change on main branch</p> line is present on the main branch, which is also the branch that we've currently switched to.
- =====: this line indicates where the changes from the current branch end and where the changes from the new branch are coming from. In our case, the change from the new branch is the <p>Conflict Demo</p> line.
- >>>>>>> conflictDemo: this indicates the name of the branch that the changes are coming from.

You can resolve the conflict by manually removing the lines that are not needed, so at the end, the file will look like this:

```
<h1>My First Feature Branch</h1>
<p>Conflict: change on main branch</p>
```

In case that you are using an IDE like VS Code, for example, it will allow you to choose which changes to keep with a click of a button.

After resolving the conflict, you will need to make another commit as the conflict is now resolved:

```
git commit -am "Resolve merge conflict"
```

Git branches and merges allow you to work on a project together with other people. One important thing to keep in mind is to make sure that you pull the changes to your local main branch on a regular basis so that it does not get behind the remote one.

A few more commands which you might find useful once you feel comfortable with what we've covered so far are the `git rebase` command and the `git cherry-pick` command, which lets you pick which commits from a specific branch you would like to carry over to your current branch.

As with everything, there are multiple ways to do a specific thing. But what I would usually do in this case I want to undo my latest commit and then commit my new changes is the following.

- Let's say that you made some changes and you committed the changes:

```
git commit -m "Committing the wrong changes"
```

- After that if you run `git log`, you will see the history of everything that has been committed to a repository.
- Unfortunately, after you commit the wrong changes, you realize that you forget to add files to the commit or forget to add a small change to committed files.
- To solve that all you need to do is make these changes and stage them by running `git add` then you can `amend` the last commit by running the following command:

```
git commit --amend
```

Note: The above command will also let you change the commit message if you need.

You need to be careful with resetting commands because this command will erase commits from the repository and delete it from the history.

Example:

```
git reset --soft HEAD~1
```

The above command will reset back with 1 point.

Note: the above would undo your commit, but it would keep your code changes if you would like to get rid of the changes as well, you need to do a hard reset: `git reset --hard HEAD~1`

Syntax:

```
git reset [--soft|--hard] [<reference-to-commit>]
```

- After that, make your new changes
- Once you are done with the changes, run `git add` to add any of the files that you would like to be included in the next commit:

```
git add .
```

- Then use `git commit` as normal to commit your new changes:

```
git commit -m "Your new commit message"
```

- After that, you could again check your history by running:

 `git log`

Here's a screenshot of the process:

```

root@do-dev:~/demo# git init .
Initialized empty Git repository in /root/demo/.git/
root@do-dev:~/demo# touch demo.txt
root@do-dev:~/demo# git add .

commit 45f651dd4e83205fe1a72ac16bf0d7a3ecfba904
Author: Bobby Iliev <bobby@bobbyiliev.com>
Date: Wed Jan 8 08:49:27 2020 +0000

First commit
root@do-dev:~/demo# █

```

Note: You can reset your changes by more than one commit by using the following syntax:

```
git reset --soft HEAD~n
```

where **n** is the number of commits you want to reset back.

Another approach would be to use **git revert COMMIT_ID** instead.

Here is a quick video demo on how to do the above:

[Reverting changes](#)

More often than not, rather than starting a new project from scratch, you would either join a company and start working on an existing project, or you would contribute to an already established open source project. So in this case, in order to get the repository from GitHub to your local machine, you would need to use the `git clone` command.

The most straightforward way to clone your GitHub repository is to first visit the repository in your browser, and then click on the green `Code` button and choose the method that you want to use to clone the repository:

In my case, I would go for the SSH method as I already have my SSH keys configured as per chapter 14.

As I am cloning this repository [here](#), the URL would look like this:

```
git@github.com:bobbyiliev/introduction-to-bash-scripting.git
```

Once you have this in my clipboard, head back to your terminal, go to a directory where you would like to clone the repository to and then run the following command:

```
git clone git@github.com:bobbyiliev/introduction-to-bash-scripting.git
```

The output that you would get will look like this:

```
Cloning into 'introduction-to-bash-scripting'...
remote: Enumerating objects: 21, done.
remote: Counting objects: 100% (21/21), done.
remote: Compressing objects: 100% (16/16), done.
remote: Total 215 (delta 7), reused 14 (delta 4), pack-reused
194
Receiving objects: 100% (215/215), 3.08 MiB | 5.38 MiB/s,
done.
Resolving deltas: 100% (114/114), done.
```

Essentially what the `git clone` command does is to more or less download the repository from GitHub to your local folder.

Now you can start making the changes to the project by creating a new branch, writing some code, and finally committing and pushing your changes!

One important thing to keep in mind is that in case that you are not the maintainer of the repository and do not have the right to push to the repository, you would need to first fork the original repository and then clone the forked repository from your account. In the next chapter, we will go through the full process of forking a repository!

When contributing to an open-source project, you will not be able to make the changes directly to the project. Only the repository maintainers have that privilege.

What you need to do instead is to fork the specific repository, make the changes to the forked project and then submit a pull request to the original project. You will learn more about pull requests in the next chapters.

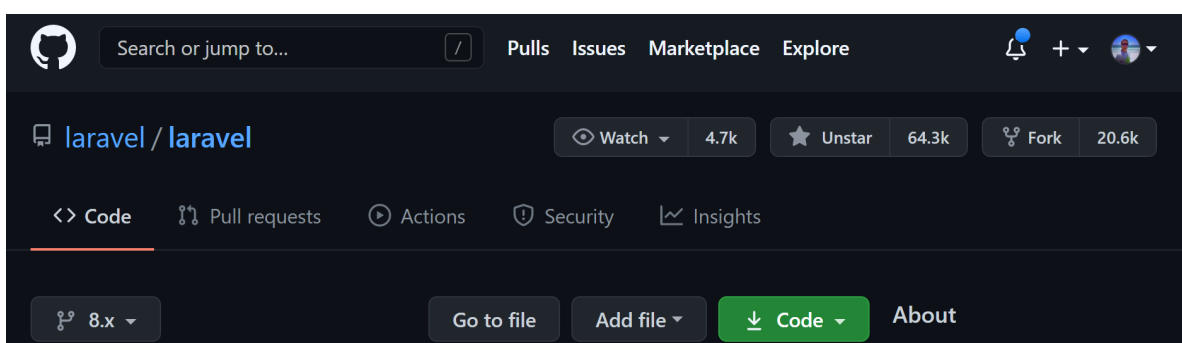

If you clone a repository that you don't have the access to and then try to push the changes directly to that repository, you would get the following error:

```
ERROR: Permission to laravel/laravel.git denied to bobbyiliev.  
Fatal: Could not read from remote repository.
```

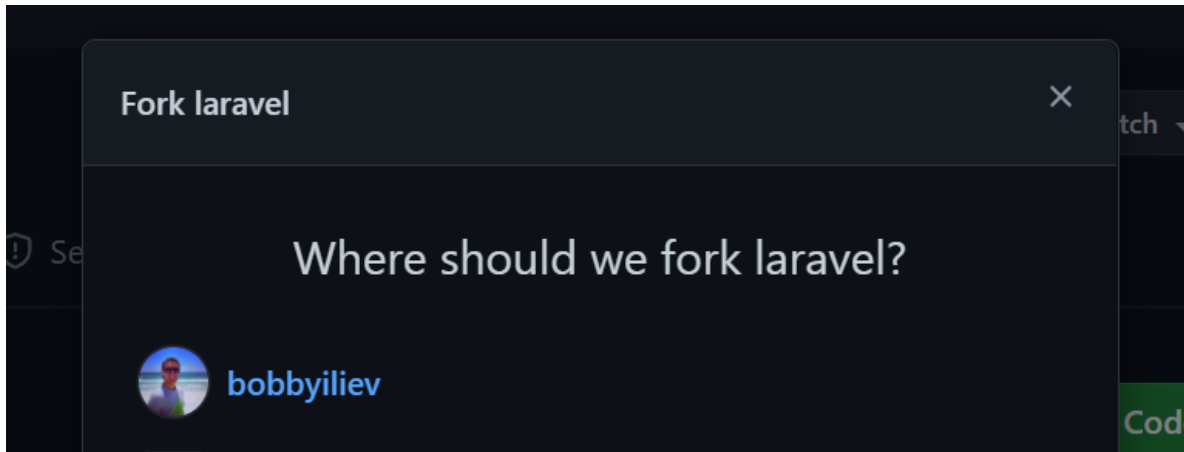

```
Please make sure you have the correct access rights  
and the repository exists.
```

This is where Forks come into play!

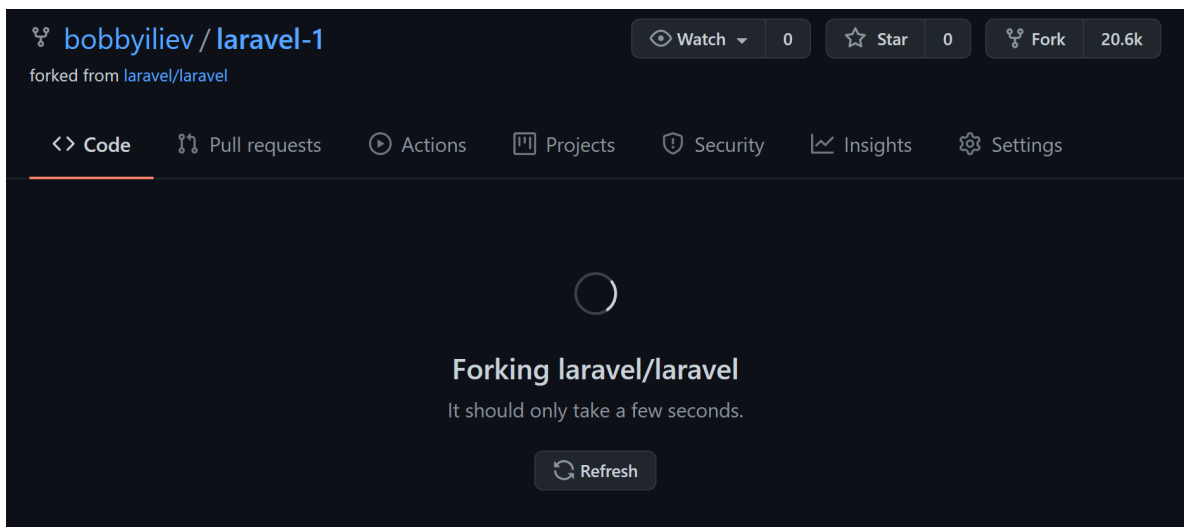

In order to fork a repository, you need to visit the repository via your browser and click on the Fork button on the top right:

Then choose the account that you want to fork the repository to:

Then it might take a few seconds for the repository to be forked under your account:

With that, you would have an exact copy of the repository in question under your account.

The benefit here is that you can now clone the forked repository under your account, make the changes to that repository as normal, and then once you are ready, you can submit a pull request to the original repository contributing your changes.

As we've now mentioned submitting pull requests a few times already, let's go ahead and learn more about pull requests in the next chapter!

Now that you know the basic commands, let's put it all together and go through a basic Git workflow.

Usually, the workflow looks something like this:

- First, you clone an existing project with the `git clone` command, or if you are starting a new project, you initialize it with the `git init` command.
- After that, before starting with your code changes, it's best to create a new Git branch where you would work on. You can do that with the `git checkout -b YOUR_BRANCH_NAME` command.
- Once you have your branch ready, you would start making the changes to your code.
- Then, once you are ready with the changes, you need to stage them with the `git add` command.
- Then, to commit/save the changes to your local Git repository, you need to run the `git commit` command and provide a descriptive commit message.
- To push your local changes to your remote GitHub project, you would use the `git push origin YOUR_BRANCH_NAME` command.
- Finally, once you've pushed your changes, you would need to submit a pull request (PR) from your branch to the main branch of the repository.
- It is considered good practice to add a couple of people as reviewers and ask them to review the changes.
- Finally, once the changes have been approved, the PR would get merged into the

main branch taking all of your changes from your branch into the main branch.

The overall process will look like this:

My advice is to create a new repository and go over this process a few times until you feel completely comfortable with all of the commands.

You already know how to merge changes from one branch to another on your local Git repository.

To do the same thing on GitHub, you would need to open a Pull Request (or a Merge Request if you are using GitLab) or a PR for short and request a merge from your feature branch to the `main` branch.

The steps that you would need to take to open a Pull Request are:

- If you are working on an open-source project that you are not the maintainer of, first fork the repository as per chapter 21. Skip this step if you are the maintainer of the repository.
- Then clone the repository locally with the `git clone` command:

```
git clone git@github.com:your_user/your_repo
```

- Create a new branch with the `git checkout` command:

```
git checkout -b branch_name
```

- Make your code changes
- Stage the changes with `git add`

```
git add .
```

- And then commit them with `git commit`:

```
git commit -m "Commit Message"
```

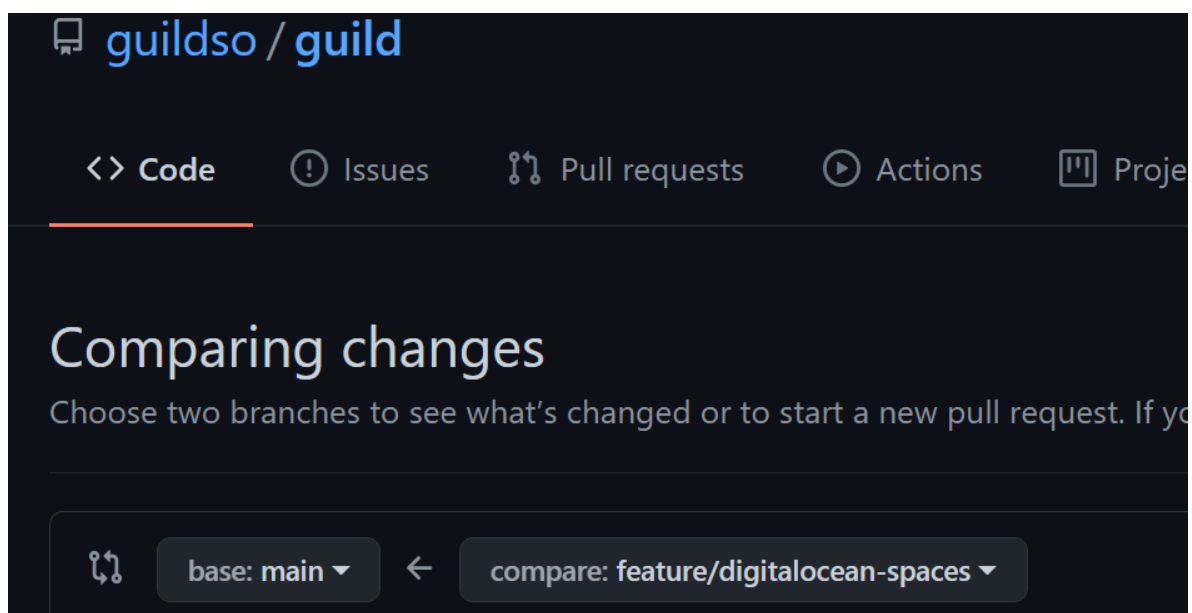

- Then push your new branch to GitHub with `git push`:

```
git push origin branch_name
```

- After that, visit the repository on GitHub and click on the **Pull Requests** button and then click on the green **New pull request** button:

- In there, choose the branch that you want to merge to and the branch that you want to merge from:

- Then review the changes and add a title and description and hit the create button
- If you are working on a project with multiple contributors, make sure to select a few reviewers. Essentially reviewers are people who you would like to review your code before it gets merged to the **main** branch.

For a visual representation of the whole process, make sure to check out this step by step tutorial as well:

- [How to Submit Your First Pull Request on GitHub](#)

As much as I love to use the terminal to do my daily tasks in the end, I would rather do multiple tasks within one window (GUI) or perform everything from the terminal itself.

In the past, I was using the text editors (vim, nano, etc.) in my terminal to edit the code in my repositories and then go along with the git client to commit my changes. Still, then I switched to Visual Studio Code to manage and develop my code.

I will recommend you to check this article on why you should use Visual Studio. It is an article from Visual Studio's website itself.

[Why you should use Visual Studio](#)

Visual Studio Code has integrated source control management (SCM) and includes Git support in-the-box. Many other source control providers are available through extensions on the VS Code Marketplace. It also has support for handling multiple Source Control providers simultaneously so you can open all of your projects at the same time and make changes whenever this is needed.

You need to install Visual Studio Code. It runs on the macOS, Linux, and Windows operating systems.

Follow the platform-specific guides below:

- [macOS](#)
- [Linux](#)
- [Windows](#)

You need to install Git first before you get these features. Make sure you install at least version 2.0.0. If you do not have git installed on your machine, feel free to check this really useful article on [How to get started with Git](#)

You need to set your username and email in the Git configuration, or git will fail back to using information from your local machine when you commit. We need to provide this information because Git embeds this information into each commit we do.

To set this, you can execute the following commands:

```
git config --global user.name "John Doe"
git config --global user.email "johnde@domain.com"
```

The information will be saved in your `~/.gitconfig` file.

```
[user]
  name = John Doe
  email = johndoe@domain.com
```

With Git installed and set up on your local machine, you are now ready to use Git for version control with Visual Studio or using the terminal.

The good thing is that Visual Studio will auto-detect if you've opened a folder that is a repository. If you've already opened a repository, it will be visible in the Source Control View.

If you haven't opened a folder yet, the Source Control view will give you the option to Open Folder from your local machine or Clone Repository.

If you select Clone Repository, you will be asked for the URL of the remote repository (for example, on GitHub) and the parent directory under which to put the local repository.

For a GitHub repository, you would find the URL from the GitHub Code dialog.

To create a branch open the command pallet:

- Windows: Ctrl + Shift + P
- Linux: Ctrl + Shift + P
- MacOS: Shift + CMD + P

And select **Git Create Branch...**

Then you just need to enter a name for the branch. Keep in mind that in the bottom left corner, you can see in which branch you are. The default one will be the main, and if you successfully create the branch, you should see the name of the newly created branch.

If you want to switch branches, you can open the command pallet and search for **Git checkout to** and then select the main branch or switch to a different branch.

If you want to speed up the process and have a predefined template for your commit messages, you can create a simple file that will contain this information.

To do that, open your terminal if you're on Linux or macOS and create the following file: `.gitmessage` in your home directory. To create the file, you can open it in your favorite text editor and then simply put the default content you would like and then just save and exit the file. Example content is:

```
cat ~/.gitmessage
```

```
#Title
```

```
#Summary of the commit
```

```
#Include Co-authored-by for all contributors.
```

To tell Git to use it as the default message that appears in your editor when you run `git commit` and set the `commit.template` configuration value:

```
$ git config --global commit.template ~/.gitmessage
$ git commit
```

If you prefer to code in Visual Studio Code and you also use version control, I will recommend you to give it a go and interact with the repositories in VS code. I believe that everyone has their own style, and they might do things differently depending on their mood as well. As long as you can add/modify your code and then commit your changes to the repository, there is no exactly correct/wrong way to achieve this. For example, you can edit your code in vim and push the changes using the git client in your terminal or do the coding in Visual Studio and then commit the changes using the terminal as well. You're free to do it the way you want it and the way you find it more convenient as well. I believe that using git within VS code can make your workflow more efficient and robust.

- [Version Control](#) - Read more about integrated Git support.
- [Setup Overview](#) - Set up and start using VS Code.
- [GitHub with Visual Studio](#) - Read more about the GitHub support in VS code
- You can also check this mini video tutorial on how to use the basics of Git version control in Visual Studio Code

Source:

- Contributed by: [Alex Georgiev](#).
- Initially posted [here](#).

The GitHub CLI or **gh** is basically GitHub on command-line.

You can interact with your GitHub account directly through your command line and manage things like pull requests, issues, and other GitHub actions.

In this tutorial, I will give a quick overview of how to install **gh** and how to use it!

As I will be using Ubuntu, to install **gh** you need to run the following commands:

```
sudo apt-key adv --keyserver keyserver.ubuntu.com --recv-key  
C99B11DEB97541F0  
sudo apt-add-repository https://cli.github.com/packages  
sudo apt update  
sudo apt install gh
```

If you are on a Mac, you can install **gh** using Homebrew:

```
brew install gh
```

For any other operating systems, I recommend following the steps from the official documentation [here](#).

Once you have **gh** installed, you can verify that it works with the following command:

```
gh --version
```

This would output the **gh** version:

```
gh version 1.0.0 (2020-09-16)  
https://github.com/cli/cli/releases/tag/v1.0.0
```

In my case, I'm running the latest **gh** v1.0.0, which got released just a couple of days ago.

Once you have **gh** installed, you need to login to your GitHub account.

To do so, you need to run the following command:

```
gh auth login
```

You will see the following output:

```
? What account do you want to log into? [Use arrows to move,
type to filter]
> GitHub.com
  GitHub Enterprise Server
```

You have an option to choose between GitHub.com or GitHub Enterprise. Click enter and then follow the authentication process.

Another useful command is the **gh help** command. This will give you a list with the available **gh** commands that you could use:

USAGE

gh <command> <subcommand> [flags]

CORE COMMANDS

gist: Create gists
issue: Manage issues
pr: Manage pull requests
release: Manage GitHub releases
repo: Create, clone, fork, and view repositories

ADDITIONAL COMMANDS

alias: Create command shortcuts
api: Make an authenticated GitHub API request
auth: Login, logout, and refresh your authentication
completion: Generate shell completion scripts
config: Manage configuration for gh
help: Help about any command

FLAGS

--help Show help for command
--version Show gh version

EXAMPLES

```
$ gh issue create  
$ gh repo clone cli/cli  
$ gh pr checkout 321
```

ENVIRONMENT VARIABLES

See 'gh help environment' for the list of supported environment variables.

LEARN MORE

Use 'gh <command> <subcommand> --help' for more information about a command.

Read the manual at <https://cli.github.com/manual>

FEEDBACK

Open an issue using 'gh issue create -R cli/cli'

Then let's clone an existing project which we will use to play with. As an example, we can use the [LaraSail](#) repository. Rather than cloning the repository using the standard `git clone` command, we will use `gh` to do so:

```
gh repo clone thedevdojo/larasail
```

You will see the following output:

```
Cloning into 'larasail'...
```

After that `cd` into that folder:

```
cd larasail
```

We are now ready to move to some of the more useful `gh` commands!

Using `gh`, you can pretty much get all of the information for your repository on GitHub without having even to leave your terminal.

Here's a list of some useful commands:

To list all open issues, run:

```
gh issue list
```

The output that you will see is:

```
Showing 4 of 4 open issues in thedevdojo/larasail

#25  Add option to automatically create database
      (enhancement)  about 3 months ago
#22  Remove PHP mcrypt as it is no longer needed
      about 3 months ago
#11  Add redis support
      about 8 months ago
#10  Wondering about the security of storing root MySQL
      password in /etc/.larasail/tmp/mysqlpass          about
      3 months ago
```

You can even create a new issue with the following command:

```
gh issue create --label bug
```

Or if you wanted to view an existing issue, you could just run:

```
gh issue view '#25'
```

This would return all of the information for that specific issue number:

```
Add option to automatically create a database
Open • bobbyiliev opened about 3 months ago • 0 comments

Labels: enhancement

Add an option to automatically create a new database, a
database user and
possibly update the database details in the .env file for a
specific project

View this issue on GitHub:
https://github.com/thedevdojo/larasail/issues/25
```

You can use the **gh repo** command to create, clone, or view an existing repository:

```
gh repo create
gh repo clone cli/cli
gh repo view --web
```

For example, if we ran the **gh repo view**, we would see the same README information for our repository directly in our terminal.

You can use the **gh pr** command with a set of arguments to fully manage your pull requests.

Some of the available options are:

checkout:	Check out a pull request in git
checks:	Show CI status for a single pull request
close:	Close a pull request
create:	Create a pull request
diff:	View changes in a pull request
list:	List and filter pull requests in this repository
merge:	Merge a pull request
ready:	Mark a pull request as ready for review
reopen:	Reopen a pull request
review:	Add a review to a pull request
status:	Show status of relevant pull requests
view:	View a pull request

With the above commands, you are ready to execute some of the main GitHub actions you would typically take directly in your terminal!

Now you know what the GitHub CLI tool is and how to use it! For more information, I would recommend checking out the official documentation here:

<https://cli.github.com/manual/>

I'm a big fan of all command-line tools! They can make your life easier and automate a lot of the daily repetitive tasks!

Initially posted here: [What is GitHub CLI and how to get started](#)

`git stash` is a handy command that helps you in cases where you might need to stash away your local changes and reset your codebase to the most recent commit in order to work on a more urgent bug/feature.

In other words, this command allows you to revert your current working directory to match the `HEAD` commit while keeping all the local modifications safe.

Once you are ready to get back to working on the code you had stashed away, just restore them with a single command!

git stash

For example, consider a file named `index.html` which has been modified since the last commit.

```
Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git status
On branch master
Changes not staged for commit:
  (use "git add <file>..." to update what will be committed)
  (use "git checkout -- <file>..." to discard changes in working directory)

        modified:   index.html

no changes added to commit (use "git add" and/or "git commit -a")

Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git stash
Saved working directory and index state WIP on master: d8bdd24 initial commit

Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git status
On branch master
nothing to commit, working tree clean
```

Notice that the running `git status` command says that there are no new changes once the `git stash` command is executed!

Here WIP stands for Work-In-Progress and these are used to index the various stashed copies of your work.

An important thing to keep in mind before stashing all new changes is that, by default, `git stash` **will not stash all the untracked and ignored files**. (Here, *untracked files* are the files that weren't part of the last commit i.e, new files in your local repo)

In case you want to include these untracked files in the stash, you'll need to add the `-u` option.

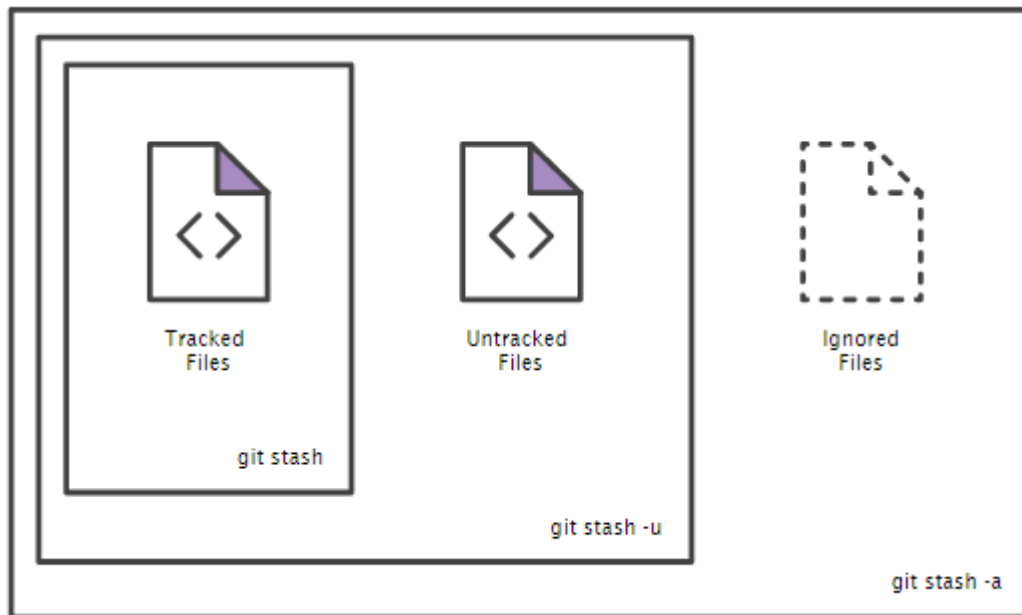

git stash -u

Similarly, all the files in the `.gitignore` file (i.e, *the ignored files*) will also be

excluded from your stash. But you can include them by using the **-a option**

```
git stash -a
```

The following illustrations depict the behaviour of the `git stash` command when the above two options are included:

git stash apply

This command is used to reapply all the local modifications done before that copy of the work was stashed.

Note that another command that can be used to achieve this is the `git stash pop` command. Here *popping* refers to the process of removing the most recent stash content and reapplying them to your working copy.

The difference between these two commands is that the `git stash pop` command **will remove these particular changes from the stash** whereas the `git stash apply` command **will retain those changes in the stash** even after restoring them.

Consider the previous example itself, in which the file `index.html` was stashed. In the following image, you can see how restoring all those changes affects your local repo.

```
Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git status
On branch master
nothing to commit, working tree clean

Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git stash apply
On branch master
Changes not staged for commit:
  (use "git add <file>..." to update what will be committed)
  (use "git checkout -- <file>..." to discard changes in working directory)

        modified:   index.html

no changes added to commit (use "git add" and/or "git commit -a")
```

But what if you have multiple stashes and aren't sure which one you want to start working on? This is where the next command comes into the picture!

Similar to the process involved in resetting the local repository to a particular commit, the first step involved in handling multiple stashes is to **take a look at the various stashes available**.

```
git stash list
```

This command shows an indexed list of all the available stashes along with a **message corresponding to their respective recent commits**.

Consider the following example wherein there are two available stashes. One, when a new script file was added and another when this script file was altered.

```
Rajat@DESKTOP-J8MKHE6 MINGW64 ~/Desktop/my-project (master)
$ git stash list
stash@{0}: WIP on master: 94e3760 alter the script file
stash@{1}: WIP on master: a628e30 add a script file
```

Note that the most recent stash is always indexed as 0.

Once you know which stash you want to restore to your local codebase, the command used to restore those modifications is:

```
git stash apply n
```

The alternative syntax used to achieve this is as follows:

```
git stash apply "stash@{n}"
```

Here **n** is the index of the stash you want to restore.

If there is a common but complex Git command that you type frequently, consider setting up a simple Git alias for it. Aliases enable more efficient workflows by requiring fewer keystrokes to execute a command. It is important to note that **there is no direct git alias command**. Aliases are created through the use of the git config command and the Git configuration files.

```
git config --global alias.co checkout
```

Now when I use the command git co, it is just as if I had typed that longer git checkout command.

```
git co -b branch1
```

Output

```
Switched to a new branch 'branch1'
```

Creating the aliases will not modify the source commands. So git checkout will still be available even though we now have the git co alias.

```
git checkout -b branch2
```

Output

```
Switched to a new branch 'branch2'
```

Aliases can also be used to wrap a sequence of Git commands into new Git command.

Rebasing is often used as an alternative to merging. Rebasing a branch updates one branch with another by applying the commits of one branch on top of the commits of another branch. For example, if working on a feature branch that is out of date with a dev branch, rebasing the feature branch onto dev will allow all the new commits from dev to be included in feature. Here's what this looks like visually:

```
git rebase feature dev
```

where branch1 is the branch we want to rebase to the master.

Many people think that **Merge** and **Rebase** commands perform the same job but actually they are completely different and we will discuss this in the following lines.

- **Merge :**

This command is used to integrate changes from some branch to another branch with keeping the merged branch at its base so you can easily return to earlier version of code if you want and the following picture show that :

Updating a Feature Branch

Lets say you're working away on a feature branch, minding your own business.

Then you notice some new commits on dev that you'd like to have in your feature

branch, since the new commits may affect how you implement the feature.

You decide to run `git rebase dev` from your feature branch to get up-to-date with dev. However when you run the rebase command, there are some conflicts between the changes you made on feature and the new commits on dev. Thankfully, the rebase process goes through each commit one at a time and so as soon as it notices a conflict on a commit, git will provide a message in the terminal outlining what files need to be resolved. Once you've resolved the conflict, you git add your changes to the commit and run `git rebase --continue` to continue the rebase process. If there are no more conflicts, you will have successfully rebased your feature branch onto dev.

Now you can continue working on your feature with the latest commits from dev included in feature and all is well again in the world. This process can repeat itself if the dev branch is updated with additional commits.

- **Rebase :**

On the other hand **Rebase** command is used to transfer the base of the branch to be based at the last commit of the current branch which make them as one branch as shown in the picture at the top.

You can also rebase a branche on another **interactively**. This means that you will be prompted for options. The basic command looks like this:

```
git rebase -i feature main
```

This will open your favorite editor (probably `vi` or `vscode`).

Let's create an example:

```
git switch main
git checkout -b feature-interactive
echo "<p>Rebasing interactively is super cool</p>" >>
feature1.html
git commit -am "Commit to test Interactive Rebase"
echo "<p>With interactive rebasing you can do really cool
stuff</p>" >> feature1.html
git commit -am "Commit to test Interactive Rebase"
```

So you are now on the `feature-interactive` branch with a commit on this branch that doesn't exist on the `main` branch, and there is a new commit on the `main` that is not in your branch.

Now using the interactive rebase command:

```
git rebase -i main
```

Your favorite editor (`vi` like here or `vscode` if you've set it up correctly) should be open with something like this:

```
pick a21b178 Commit to test Interactive Rebase
pick cd3400c Commit to test Interactive Rebase
```

```
# Rebase 1d152d4..a21b178 onto 1d152d4
#
# p, pick <commit> = use commit
# r, reword <commit> = use commit, but edit the commit message
# e, edit <commit> = use commit, but stop for amending
# s, squash <commit> = use commit, but meld into previous
commit
# f, fixup <commit> = like "squash", but discard this commit's
log message
# x, exec <command> = run command (the rest of the line) using
shell
# b, break = stop here (continue rebase later with 'git rebase
--continue')
# d, drop <commit> = remove commit
# l, label <label> = label current HEAD with a name
# t, reset <label> = reset HEAD to a label
# m, merge [-C <commit> | -c <commit>] <label> [# <oneline>]
# .      create a merge commit using the original merge
commit's
# .      message (or the oneline, if no original merge commit
was
# .      specified). Use -c <commit> to reword the commit
message.
#
# These lines can be re-ordered; they are executed from top to
bottom.
#
# If you remove a line here THAT COMMIT WILL BE LOST.
#
# However, if you remove everything, the rebase will be
aborted.
#
# Note that empty commits are commented out
```

As you can see here, the first lines are the commits you made in this **feature-interactive** branche. Then, the remaining of the file is the help message. If you look at this help message closely, you will notice that there are plenty of options. To use them all you need to do is to prefix the commit line you want to work on by the name of the command or its shortcut letter.

The basic command is **pick**, meaning that the current rebase will use these two

commits to do its work.

In our case, if you want to update the commit message of the second commit, you would update this file like this (we just show the first lines as the remaining are not updates):

```
pick a21b178 Commit to test Interactive Rebase
r cd3400c Commit to test Interactive Rebase

# Rebase 1d152d4..a21b178 onto 1d152d4
#
...
```

Then you would save the file, as it is **vi** here, you would hit the key **:** and type **wq**. You should now see another file opened in the same editor, where you can edit your commit message, then save the file and that's it.

You can look at the result with the following command:

```
git log
```

Now that you now the basics on how to use this command, take a look at the help message. There are some usefull commend in there. My favorites are the **reword**, **fixup** and **drop** but feel free to experiment by yourself.

`git switch` is not a new feature but an additional command to switch/change branch feature which is already available in the overloaded `git checkout` command. That's why, pretty recently, the Git community decided to publish a new command: `git switch`. As the name implies.

```
git switch <branch-name>
```

As you can see, its usage is very straightforward and similar to "git checkout". But the huge advantage over the "checkout" command is that "switch" does NOT have a million other meanings and capabilities.

As it is quite a new member of the Git command family, you should check if your Git installation already includes it.

In some scenarios, it might be necessary for you to switch back and forth between two branches repeatedly. Instead of always writing out the branch names in full, you can simply use the following shortcut:

```
git switch -
```

Using the dash character as its only parameter, the "git switch" command will check out the previously active branch. As said, this can come in very handy if you have to go back and forth between two branches a bunch of times.

Apart from looking awesome, a good GitHub profile shows people what you can do and gives you a chance to show it off. Also, job applications often include a section to add your GitHub profile link so this can be your chance to shine ☺

[View full profile](#)

To create a GitHub profile, you need to understand Markdown. Markdown is a lightweight markup language for creating formatted text using a plain-text editor. Check out this [Markdown Cheatsheet](#).

First of all you need to create a new repository. Use this link <https://github.com/new> to do so. You must name your repository the same as your GitHub username as shown below:

You will discover your secret/special repository! Make the repository public and select add a README file. Then you are done creating your repository. I recommend making your repository private whilst you work on it and then making it public once complete. Now time to add content and make it look awesome.

Tip: When working on a markdown file in your development environment, you can preview what the page will look like by pressing **CMD+Shift+V** or **Ctrl+Shift+V**

The first thing people on your profile notice is the header. Perhaps you could add a photo of something you love, your hobby, art that inspires you, an image of some code you worked on, etc. You could even have your profile picture match it. I recommend an actual photo of yourself, rather than a cartoon. The markdown needed is:

```
![[Repository Banner](https://raw.githubusercontent.com/GITHUB-
USERNAME/GITHUB-USERNAME/banner_photo.png)]
```

Here is a website that allows you to generate header images for your GitHub profile READMEs. <https://reheader.glitch.me/>

Say hello to your visitors. Write an introductory paragraph. Tell them a bit about yourself, where you are from, what inspires you. This section is where you can let your

personality shine though.

You can show visitors to your profile what you are up to and what you are working on. This is a great way for them to get to know a bit more about you.

- ☐ I'm interested in...
- ☐ I'm currently working on...
- ☐ I'm currently studying...
- ☐ I'm looking to...
- ☐ I'm looking for help with...
- ☐ Ask me about...
- ☐ Fun fact:...

You can display your GitHub stats on your profile. These include displaying total commits made, total pull requests, total issues etc. Check out these cool themes to display your statistics:

[Click here](#) to use one of these cool themes

Adding social media buttons is a great way to direct visitors or even employers to your

social media platforms. For example to add Twitter:

```
[![Twitter  
URL](https://img.shields.io/twitter/url/https/twitter.com/USER  
-  
NAME.svg?style=social&label=Twitter)](https://twitter.com/USER  
-NAME)
```

As the number of repositories you've created or contributed to grows, you might want to showcase a few of these repositories straight on your profile. This feature is extra useful when you want to present your portfolio to a potential employer and want them to see the work you are proudest of first!

This is how you do it:

In the top right corner, click on your profile photo and select "Your profile" from the menu:

In the section saying "Popular repositories" or "Pinned", click on "Customize your pins":

After the previous step, the "Edit pinned items" modal will open. Here, you can choose a combination of up to six repositories and/or gists to display:

Once you've decided which repositories you want to pin, click "Save pins".

Check out these useful links to inspire you, to help you with your GitHub profile:

- <https://github.com/abhisheknaidu/awesome-github-profile-readme>
- <https://github.com/elangosundar/awesome-README-templates>

This is a fun project to work on. Be creative! There is a lot more you can add to your profile. From adding different statistics, technologies & tools you use, emoji GIFs, etc. You can ask friends or other developers their opinions of your GitHub profile. Remember don't overdo it. No one wants super fast animations or flashing images that will hurt their eyes. Think of nice color themes, what works well together, and add a nice profile pic. Good luck!

Here is a list of the Git commands mentioned throughout the eBook

- Git Configuration

Before you initialize a new git repository or start making commits, you should set up your git identity.

To change the name that is associated with your commits, you can use the `git config` command:

```
git config --global user.name "Your Name"
```

The same would go for changing your email address associated with your commits as well:

```
git config --global user.email "yourmail@example.com"
```

That way, once you have the above configured when you make a commit and then check the git log, you will be able to see that the commit is associated with the details that you've configured above.

```
git log
```

In my case the output looks like this:

```
commit 45f96b8c2ef143011f11b5f6cc7a3ae20db5349d (HEAD -> main,  
origin/master, origin/HEAD)  
Author: Bobby Iliev <bobby@bobbyiliev.com>  
Date:   Fri Jun 19 17:03:53 2020 +0300
```

```
    Nginx server name for www version (#26)
```

To initialize a new local git project, open your git or bash terminal, `cd` to the directory that you would like your project to be stored at, and then run:

```
git init .
```

If you already have an existing project in GitHub, for example, you can clone it by using the git clone command:

```
git clone your_project_url
```

To check the current status of your local git repository, you need to use the following command:

```
git status
```

This is probably one of the most used commands as you would need to check the status of your local repository quite often to be able to tell what files have been changed, staged, or deleted.

Let's say that you have a static HTML project, and you have already initialized your git repository.

After that, at a later stage, you decide to add a new HTML file called `about-me.html`, then you've added some HTML code in there already. To add your new file so that it is also tracked in git, you first need to use the `git add` command:

```
git add file_name
```

This will stage your new file, which essentially means that the next time you make a commit, the change will be part of the commit.

To check that, you can again run the `git status` command:

```
git status
```

You will see the following output:

```
On branch main
Your branch is up to date with 'origin/main'.

Changes to be committed:
  (use "git reset HEAD <file>..." to unstage)

    new file:   about-me.html
```

To remove a file from your git project, use the following command:

```
git rm some_file.txt
```

Then after that, if you run `git status` again, you will see that the `some_file.txt` file has been deleted:

```
On branch main
Your branch is up to date with 'origin/main'.

Changes to be committed:
  (use "git reset HEAD <file>..." to unstage)

        deleted:    some_file.txt
```

In case that you've made a mistake and you want to discard the changes for a specific file and reset the content of that file as it was in the latest commit, you need to use the command below:

```
git checkout -- file_name
```

This is a convenient command as you can quickly revert a file to its original content.

Once you've made your changes and you've staged them with the `git add` command, you need to commit your changes.

To do so, you have to use the `git commit` command:

```
git commit
```

This will open a text editor where you could type your commit message.

Instead, you could use the `-m` flag to specify the commit message directly in your command:

```
git commit -m "Nice commit message here"
```

To list all of the available local branches, just run the following command:

```
git branch -a
```

You would get a list of both local and remote branches, the output would look like this:

```
bugfix/nginx-www-server-name
develop
* main
remotes/origin/HEAD -> origin/master
remotes/origin/bugfix/nginx-www-server-name
remotes/origin/develop
remotes/origin/main
```

The **remotes** keyword indicates that those branches are remote branches.

If you are working together with a team of developers working on the same project, more often than not, you would need to fetch the changes that your colleagues have made to have them locally on your PC.

To do that, all you need to do is to use the **git pull** command:

```
git pull origin branch_name
```

Note that this will also merge the new changes to the current branch that you are checked into.

To create a new branch, all you need to do is use the **git branch** command:

```
git branch branch_name
```

Instead of the above, I prefer using the following command as it creates a new branch and also switches you to the newly created branch:

```
git checkout -b branch_name
```

If the `branch_name` already exists, you would get a warning that the branch name exists and you would not be checked out to it,

Then finally, once you've made all of your changes, you've staged them with the `git add .` command, and then you committed the changes with the `git commit` command, you have to push those changes to the remote git repository.

To do so, just use the `git push` command:

```
git push origin branch_name
```

```
git branch -d branch_name
```

```
git checkout branch_name
```

As mentioned above, if you add the `-b` flag, it would create the branch if it does not exist.

Knowing the above commands will let you manage your project like a pro!

If you are interested in improving your command line skills in general, I strongly recommend this [Linux Command-line basics course here!](#)

Congratulations! You have just completed the Git basics guide!

If you found this useful, be sure to star the project on [GitHub](#)!

If you have any suggestions for improvements, make sure to contribute pull requests or open issues.

In this introduction to Git and GitHub eBook, we just covered the basics, but you still have enough under your belt to start using Git and start contributing to some awesome open source projects!

As the next step, try to create a GitHub project, clone it locally and push a project that you've been working on to GitHub! I could also recommend the following [GitHub training here](#).

In case that this eBook inspired you to contribute to some amazing open-source project, make sure to tweet about it and tag [@bobbyiliev](#) so that we can check it out!

Congrats again on completing this eBook!
